1. Introduction

The stark racial disparities in disease incidence and health outcomes among American women remain a persistent public health challenge. For example, preterm birth incidence is approximately 60% higher in non-Hispanic Black women relative to non-Hispanic White women. These disparities likely result from complex interactions between genetic, social, lifestyle, and environmental risk factors. The influence of environmental risk factors, such as chemical exposure, however, may be substantial and is poorly understood.

Objective: We quantitatively evaluated chemical-exposure disparities by race/ethnicity, life stage, and time in United States (US) women (n = 38,080) by using biomarker data for 143 chemicals from the National Health and Nutrition Examination Survey (NHANES) 1999–2014.

Methods: We applied a series of survey-weighted, generalized linear models using data from the entire NHANES women population along with cycle and age-group stratified subpopulations. The outcome was chemical biomarker concentration, and the main predictor was race/ethnicity with adjustment for age, socioeconomic status, smoking habits, and NHANES cycle.

Results: Compared to non-Hispanic White women, the highest disparities were observed for non-Hispanic Black, Mexican American, Other Hispanic, and Other Race/Multi-Racial women with higher levels of pesticides and their metabolites, including 2,5-dichlorophenol, o,p'-DDE, beta-hexachlorocyclohexane, and 2,4-dichlorophenol, along with personal care and consumer product compounds, including parabens and monoethyl phthalate, as well as several metals, such as mercury and arsenic. Moreover, for Mexican American, Other Hispanic, and non-Hispanic black women, there were several exposure disparities that persisted across age groups, such as higher 2,4- and 2,5-dichlorophenol concentrations. Exposure levels for methyl and propyl parabens, however, were the highest in non-Hispanic black compared to non-Hispanic white children with average differences exceeding 4-fold. Exposure disparities for methyl and propyl parabens are increasing over time in Other Race/Multi-Racial women while fluctuating for non-Hispanic Black, Mexican American, and Other Hispanic. Cotinine levels are among the highest in Non-Hispanic White women compared to Mexican American and Other Hispanic women with disparities plateauing and increasing, respectively.

Discussion: We systematically evaluated differences in chemical exposures across women of various race/ethnic groups and across age groups and time. Our findings could help inform chemical prioritization in designing epidemiological and toxicological studies. In addition, they could help guide public health interventions to reduce environmental and health disparities across populations.
women (Culhane and Goldenberg, 2011). Non-Hispanic Black and Hispanic women are at increased risk of being diagnosed with developing dysglycemia (Marcinkevage et al., 2013) and diabetes (Cowie et al., 2009), relative to non-Hispanic White women. Non-Hispanic Black women are also 2–3 times more likely to develop the most aggressive subtype of breast cancer, triple negative, compared to non-Hispanic White women (Carey et al., 2006; Stark et al., 2010). Furthermore, relative to non-Hispanic White women, non-Hispanic Black women are also 2.4 times more likely to die of breast cancer after being diagnosed with the pre-invasive lesion, ductal carcinoma in situ (Narod et al., 2015). Recent statistics from the American Cancer Society also show variation in trends in breast cancer incidence rates by race/ethnicity in US women from 2005 to 2014. Specifically, breast cancer incidence rates are increasing in Asian (1.7% per year), non-Hispanic Black (0.4% per year), and Hispanic (0.3% per year) women, while rates remain stable in non-Hispanic White and American Indian/Alaska Native women (DeSantis et al., 2017). Dementia rates also vary by race/ethnicity, with rates highest in non-Hispanic black women, followed by American Indian/Alaskan native, Latina, Pacific Islander, non-Hispanic White, and lowest in Asian American women (Mayeda et al., 2016). These rates vary 60% between African American and Asian American women. Reproductive outcomes are also significantly different by race/ethnicity, with studies reporting increased incidence of gestational diabetes in South and Central Asian American women (Thorpe et al., 2005) and Black and Hispanic women (Tanaka et al., 2007). Collectively, these findings suggest profound racial disparities in disease outcomes that manifest throughout the life course. Understanding the etiological factors driving these health disparities is essential for informing public health interventions seeking to promote health equity.

While health disparities are likely due to complex interactions between genetic, social, and lifestyle factors, the impact of genetic variation on disease disparities appears to be minor (Braun, 2007; Cooper et al., 2003; Diez Roux, 2012). For example, a meta-analysis of genetic factors underlying racial disparities in cardiovascular disease failed to identify heterogeneity of genetic risk factors by race/ethnicity (Kaufman et al., 2015). These findings of a modest genetic impact on differential cardiovascular disease risk by race/ethnicity are consistent with genome-wide association studies. A study found that variants with the strongest association with blood pressure explain, in aggregate, less than 5% of the phenotypic variance (Ehret et al., 2011). Moreover, a meta-analysis of genetic risk factors and cancer disparities reported similar findings, with almost no heterogeneity in cancer risk alleles by race/ethnicity (Jing et al., 2014).

The limited impact of genetic risk factors in explaining health disparities points towards environmental risk factors as major determinants. Indeed, estimates of environmental factors on chronic disease suggest that 70–90% of risk is due to environmental exposures (Lim et al., 2012; Rappaport and Smith, 2010). A mechanistic understanding of racial disparities in disease therefore requires a characterization of differences in environmental risk factors. In particular, differences in chemical exposures have been hypothesized to be important etiologic factors in racial disparities in disease rates (Hoover et al., 2012; Juarez and Matthews-Juarez, 2018; Ruiz et al., 2018; Wang et al., 2016; Zota and Shamasunder, 2017).

To investigate the influence of environmental risk factors on health disparities, the goal of this study was to conduct a comprehensive analysis of racial disparities in chemical biomarker concentrations among US women. To accomplish this, we leveraged data from the National Health and Nutrition Examination Survey (NHANES), an ongoing population-based health study conducted by the US Centers for Disease Control and Prevention (CDC). Additionally, we developed visualizations to highlight differences in biomarker concentrations across races, age groups, and time, by defining the relative magnitude of exposure disparities for individual chemicals and chemical families.

2. Methods

2.1. Study population

NHANES is a cross-sectional study designed for collecting data on demographic, socioeconomic, dietary, and health-related characteristics in the non-institutionalized, civilian US population. For this analysis, we used the continuous NHANES data on chemical biomarkers and demographics, which were collected from 1999 to 2014 with 82,091 participants initially. We excluded participants for not having any data on chemical biomarkers (N = 7,001), resulting in a sample size of 75,090 study participants. Since this analysis is focused on measuring chemical disparities in US women, we excluded male participants (N = 37,010), leading to a final sample size of 38,080 female participants. For a given chemical, we also excluded participants with missing data on any of the following covariates: race/ethnicity, age, NHANES cycles, poverty income ratio, cotinine levels, and urinary creatinine. Numbers of participants with complete data for a given chemical are tabulated in Excel Table S1. These exclusion and inclusion criteria are delineated in Fig. 1.

2.2. Chemical biomarker measurements

This section along with Fig. 1 delineates the curation process for selecting chemical biomarkers to include for analysis. First, we excluded biomarkers that are not indicative of chemical exposures (n = 99). Next, we corrected for differences in chemical codenames by using a unique codename for each biomarker (n = 36). We gave preference to lipid-adjusted data and therefore excluded non-lipid adjusted chemical biomarkers (n = 79) when both types of data were provided for a given chemical. We replaced all measurements below the limit of detection (LOD) with LOD/$\sqrt{2}$ as recommended by the CDC (CDC, 2009). This approximates a lognormal distribution, so that reasonably unbiased means and standard deviations are produced (Hornung and Reed, 1990). There were also instances in which urinary cadmium concentrations were recorded as 0 ng/mL due to interference with molybdenum oxide (NCHS, 2005a, 2005b). We replaced such values with LOD/$\sqrt{2}$ if the participant’s urinary cadmium level was under the LOD or otherwise excluded. We calculated detection frequencies for each chemical biomarker (Excel Table S2) and excluded biomarkers with detection frequencies of 50% or less (n = 182) across all study participants. As we have reported previously, across the NHANES cycles, improvements in laboratory technology can change the LOD and thus lead to differences in detection frequencies by NHANES cycle (Nguyen et al., 2019). To limit bias from these changing LODs over time, we calculated detection frequencies by NHANES cycle (Excel Table S2) for each chemical biomarker and excluded measurements where the LOD changed by over an order of magnitude (Excel Table S3) and detection frequencies changed over time (Nguyen et al., 2019). For instance, percentages of participants with PCB 199 measurements above LODs for Cycle 2 and Cycle 3 are 36.2% and 84.9%, respectively, and the LOD for Cycle 2 and Cycle 3 were 10.50 ng/g and 0.40 ng/g, respectively. As such, measurements from Cycle 2 for PCB 199 were excluded. Measurements from given cycles for several PCBs, Dioxins, Furans, Phytoestrogens, and VOCs along with Parathionphenol, 2-napthol, 1-pyrene and 9-pyrene (n = 449,396 total data points) were therefore also excluded based on these criteria (Excel Table S4). The final dataset for analysis consisted of 143 chemical biomarkers from 16 different chemical classes (Excel Table S5). These chemical classes were: Acrylamide, Brominated Flame Retardants (BFR), Phosphate Flame Retardants (PFR), Dioxins, Furans, Metals, Other, Personal Care & Consumer Product Compounds, Pesticides, Phthalates & Plasticizers, Phytoestrogens, Polyaromatic Hydrocarbons (PAH), Polychlorinated Biphenyls (PCB), Per- and Polyfluoroalkyl Substances (PFAS), Smoking Related Compounds, and Volatile Organic Compounds (VOC).
We performed all analyses using R version 3.6.0. Given the NHANES complex sampling design, we applied appropriate survey weights in our statistical models to produce estimates representative of the non-institutionalized, civilian US population. Applying the appropriate survey weights involved selecting the weights of the smallest analysis subpopulation (NCHS, 2018). For example, there are two types of survey weights that can be used for conducting an analysis with total arsenic: W TSA2YR or W TM E C2YR. W TMEC2YR is the NHANES codename for survey weights for all participants whose measurements were taken in a Mobile Exam Center (MEC). W TSA2YR is similar to W TMEC2YR with the exception that the survey weights are only for participants who belong to subsample A, which is a smaller subpopulation with measurements for total arsenic. Since W TSA2YR pertains to the smaller analysis subpopulation, W TSA2YR is the appropriate survey weight to apply for an analysis on total arsenic. The appropriate survey weights are listed in the original NHANES files containing the measurements for the chemical biomarker. If the survey weights are not listed for a given chemical, then we use WTMEC2YR as the default. Conducting an analysis across several NHANES cycles may require the use of different survey weights (NCHS, 2018). For instance, a statistical model for total arsenic requires using only one type of survey weights (W TSA2YR). But a statistical model for triclosan requires three different types of survey weights (W TSA2YR, W TS B2YR, W TS C2YR), since in each NHANES cycle, a different subpopulation of NHANES is measured for triclosan. To account for NHANES sampling design and use the appropriate survey weights, we developed two databases. The first was a database of codenames indicating the appropriate survey weights for each chemical biomarker and NHANES cycle (Excel Table S6). For several of the Per- and Polyfluoroalkyl Substance (PFAS), there were two different type of survey weights available within the same cycle (one for children aged 3–11 and the other for participants aged 12 and older). Therefore, we developed another database of codenames indicating which additional survey weights to use when generalizing these results for PFASs (Excel Table S7).

Using multivariate regression models, we evaluated differences in biomarker concentrations in blood and urine by race after log-transforming the data. We included log-transformed levels of cotinine as a covariate to represent smoking (Benowitz, 1999), and creatinine levels to adjust for urine dilution and flow differences (Barr et al., 2005). We modeled poverty income ratio (PIR) as a surrogate variable for socioeconomic status. PIR is the ratio of household income and poverty threshold adjusted for family size and inflation. First, we examined the racial differences in chemical biomarker levels by performing a series of chemical-specific regression models with the main predictor being race/ethnicity (categorical), adjusting for age (continuous), NHANES cycle (continuous), PIR (continuous), and cotinine (continuous) as described in Eq. (1).

$$\text{Log}10(X_{\text{Chemical Concentration}}) = \beta_{\text{race/ethnicity}_j}X_{\text{race/ethnicity}_j} + \beta_{\text{sex}}X_{\text{sex}} + \beta_{\text{age}}X_{\text{age}} + \beta_{\text{PIR}}X_{\text{PIR}} + \beta_{\text{creatinine}}X_{\text{creatinine}} + \beta_{\text{cotinine}}X_{\text{cotinine}} + \alpha$$  

Here, $X_{\text{Chemical Concentration}}$ is the log-transformed, unadjusted chemical biomarker concentration for all participants, $X_i$, where $i \in \{\text{race/ethnicity}_j, \text{age}, \text{sex}, \text{cycle}, \text{PIR}, \text{cotinine}, \text{creatinine}\}$, is the $i$th covariate for all participants, $\beta$ is the linear regression coefficient for the $i$th covariate, and $\alpha$ is the intercept. $X_{\text{race/ethnicity}_j}$, where $j \in \{\text{Mexican Americans, Other Hispanics, Non-Hispanic Black, Other Race/Multiracial}\}$ for 1999–2014, is the race covariate for comparing the $j$th race to the reference group of Non-Hispanic Whites. For chemical biomarkers which were measured in urine, we further corrected the regression models by adjusting for urinary creatinine levels (continuous). For the analyses where cotinine concentration was the outcome, the regression models were not further corrected for smoking. Prior to 2011, Asian Americans were categorized in Other Race/Multiracial category. Accordingly, to evaluate chemical exposure disparities in Asian American women, we also applied Eq. (1) to the 2011–2014 data. Then to determine whether racial disparities are driven by differences in socioeconomic status, we conducted a sensitivity analysis to observe how the race coefficients change with and without adjustment.
for PIR in the regression models. The coefficient for \( j \)th race represents the difference in log-transformed chemical biomarker concentration between the \( j \)th race and the reference group of Non-Hispanic Whites. As we are making multiple comparisons across chemical biomarkers and races, we have an increased probability of detecting false positives, i.e. a high false positive rate. To identify significant comparisons while maintaining a lower false positive rate, we used the False Detection Rate (FDR) method on the p-values of the linear regression race-coefficients (Benjamini and Hochberg, 1995).

We are interested in understanding how the racial disparities are influenced by reproductive and nutritional factors such as parity, breastfeeding, menopause/hysterectomy status, and iron deficiency, which may impact toxicant absorption and excretion. We used the reproductive health questionnaire on reasons for having period irregularities and another questionnaire on having regular periods in past 12 months to classify participants as having menopause/hysterectomy, otherwise with irregular periods, or otherwise with regular periods (reference group). Parity (continuous) is defined from the questionnaire on the number of pregnancies resulting in live births. We used parity and a questionnaire asking whether the mother breastfed her children for at least a month to categorize participants into three categories: breastfed, did not breastfeed her children, and did not breastfeed as she does not have children (reference group). We used sex-specific thresholds for hemoglobin levels (hemoglobin < 13.5 g/dL for men and < 12 g/dL for women) (American Society of Hematology, 2020) to classify participants as iron deficient or not (reference group). To determine whether the frequency distribution of these variables differ by race, we conducted a Chi-Square test on the categorical variables and a one-way ANOVA test on parity. To characterize how the estimates of racial disparities change when a given reproductive or nutritional factor is included in the regression model, we conducted a series of regression models with the outcome variable as chemical concentrations and the main predictor as race/ethnicity (categorical) while adjusting for age (continuous), NHANES cycle (continuous), PIR (continuous), cotinine (continuous), creatinine (continuous), and an \( f \)th reproductive or nutritional factor from the set of parity (continuous), breastfeeding (categorical), menopause/hysterectomy (categorical), iron deficiency (categorical) as described in Eq. (2).

\[
\log_{10}(X_{\text{Chemical Concentration}}) = \beta_{\text{race/ethnicity},j}(X_{\text{race/ethnicity},j}) + \beta_{\text{age},k}(X_{\text{age},k}) + \beta_{\text{cycle},c}(X_{\text{cycle},c}) + \beta_{\text{cotinine},l}(X_{\text{cotinine},l}) + \beta_{\text{creatinine},k}(X_{\text{creatinine},k}) + \beta_{\text{factor},f}(X_{\text{factor},f}) + \alpha
\]

(2)

For example, if \( f = \text{parity} \), the \( X_{\text{factor},f} \) refers to the number of pregnancies resulting in live birth for all participants. \( \beta_{\text{factor},f=\text{parity}} \) is interpreted as the change in log-transformed chemical biomarker concentration for every successful pregnancy. Now, if \( f = \text{iron deficiency} \), then \( X_{\text{factor},f=\text{iron deficiency}} \) indicates whether a participant is iron deficient or not for all participants. \( \beta_{\text{factor},f=\text{iron deficiency}} \) is interpreted as the difference in log-transformed chemical biomarker concentration between iron deficient participants and the reference group of participants who are not. The interpretations for menopause/hysterectomy status and breastfeeding status are similar to that of iron deficiency.

To evaluate how these racial differences in chemical exposures differ by age group, we conducted stratified analyses by age groups in the 1999–2014 data. We defined 4 age groups: 0–11, 12–19, 20–50, and 51–85. For each age group with chemical biomarker measurements, we performed a chemical-specific linear regression with the main predictor as race/ethnicity (categorical) and adjusted for age (continuous), NHANES cycle (continuous), PIR (continuous), cotinine (continuous), and creatinine (continuous), stratified by age group described in Eq. (3).

\[
\log_{10}(X_{\text{Chemical Concentration}}[\text{age group} = k]) = \beta_{\text{race/ethnicity},j,k}(X_{\text{race/ethnicity},j}[\text{age group} = k]) + \beta_{\text{age},k}(X_{\text{age},k}[\text{age group} = k]) + \beta_{\text{cycle},c}(X_{\text{cycle},c}[\text{age group} = k]) + \beta_{\text{cotinine},l}(X_{\text{cotinine},l}[\text{age group} = k]) + \beta_{\text{creatinine},k}(X_{\text{creatinine},k}[\text{age group} = k]) + \alpha
\]

(3)

Here, \( k \) is an available age group from the set of \{0–11, 12–19, 20–50, 51–85\}. \( X_{\text{Chemical Concentration}}[\text{age group} = k] \) is the log-transformed, unadjusted chemical biomarker concentration for all participants with ages in the \( k \)th age groups, \( X_{i,k} \), where \( i \in \{\text{race/ethnicity, j, age, sex, cycle}, \text{PIR, cotinine, creatinine}\} \), is the \( i \) covariate for all participants with ages with the \( k \)th age group, \( \beta_{i,k} \) is the linear regression coefficient for the \( i \) covariate and \( k \)th age group, and \( \alpha \) is the intercept. \( X_{\text{race/ethnicity},j,k} \), where \( j \in \{\text{Mexican Americans, Other Hispanics, Non-Hispanic Black, Other Race/Multiracial}\} \), is the race covariate for comparing the race to the reference group of Non-Hispanic Whites in the \( k \)th age group. To account for multiple comparisons, we used an FDR method on the p-values of the linear regression race-coefficients across all age groups (Benjamini and Hochberg, 1995).

We excluded measurements from Cycle 2 for Blood Bromodichloromethane, Cycle 2 for Blood Chloroform, and Cycle 6 for Blood Toluene due to having an error in the statistical program R when accounting for the sampling design. We excluded measurements from Cycle 2 for 3-fluoranthene as there is only one person with measurements for this chemical in Cycle 2. For each NHANES cycle with chemical biomarker measurements, we performed a chemical-specific linear regression with the main predictor as race/ethnicity (categorical) and adjusted for age (continuous), PIR (continuous), cotinine (continuous), and creatinine (continuous) as described in Eq. (4), [\text{cycle} = c\}] denotes the inclusion of participants who have chemical biomarker measurements in the \( c \)th cycle. We used an FDR method on the p-values of the coefficients to account for multiple comparisons across all races and NHANES cycles.

\[
\log_{10}(X_{\text{Chemical Concentration}}[\text{cycle} = c]) = \beta_{\text{race/ethnicity},j,c}(X_{\text{race/ethnicity},j}[\text{cycle} = c]) + \beta_{\text{age},c}(X_{\text{age},c}[\text{cycle} = c]) + \beta_{\text{cycle},c}(X_{\text{cycle},c}[\text{cycle} = c]) + \beta_{\text{cotinine},c}(X_{\text{cotinine},c}[\text{cycle} = c]) + \beta_{\text{creatinine},c}(X_{\text{creatinine},c}[\text{cycle} = c]) + \alpha
\]

(4)

3. Results

Table 1 displays demographic characteristics of the study population. The study population includes 38,080 female study participants of ages 1–85 years, with a median age of 26. Using a series of covariate adjusted regression models, we first calculated the fold-difference in chemical biomarker concentrations by race across the entire study population. These regression results are presented in graphical format in
In order to more clearly visualize the differences in chemical biomarkers by race/ethnicity, we generated volcano plots, which are displayed in Fig. 3. The x-axis of these plots depicts the fold difference in average chemical biomarker concentration between each race/ethnicity and non-Hispanic White women. The y-axis reflects the negative log10 transformation of the FDR-adjusted p-value from the regression analysis for that chemical biomarker. As shown in Fig. 3A, non-Hispanic Black, Mexican American, Other Hispanic, and other race/multiracial women had the highest levels of cotinine, a smoking biomarker, relative to non-Hispanic White women. Conversely, the smoking biomarker, NNAL, was significantly lower in Other Hispanic women. Fig. 3D shows a distinct exposure pattern in women of other race/ethnicity or multiracial women. Here, levels of heavy metals, including cadmium, mercury, and multiple arsenic biomarkers, are significantly elevated relative to non-Hispanic White women. Conversely, the smoking biomarkers, NNAL and cotinine, are significantly lower in Other Hispanic women. Fig. 3D also shows that either exposure differences between races for these chemicals are mediated by PIR, and/or exposure differences are explained by interactions between race and socioeconomic status. To visualize differences in chemical biomarker concentrations by race across a gradient of income for a few selected biomarkers, we generated violin plots of the chemical biomarker distribution stratified by categories of PIR for each race/ethnicity (Fig. S2). For benzophenone-3 and cotinine (Fig. S2A and S2B), the trends of biomarker concentrations across the PIR categories and the average concentrations within the same PIR categories differ by race. This is similar for ethylparaben (Fig. S2C), but differences are not as drastic. On the other hand, mercury (Fig. S2D) along with other remaining chemicals demonstrated a very different pattern from those of the previously mentioned substances. Across all races, the trends across PIR categories are similar for mercury, but within the same PIR category, there are differences in biomarker concentrations by race, suggesting that many chemical exposures disparities by race are independent of PIR.

We also characterized how reproductive and nutritional factors such as parity, breastfeeding, menopause/hysterectomy status, and iron deficiency may influence racial disparities in chemical exposures, as well as to account for racial variations in these factors in our models (Aliyu et al., 2005; Henderson et al., 2008; Zakai et al., 2008). There are significant differences by race in all studied reproductive and nutritional factors with the p-values listed as the following: parity (p-value = 6.59e-95), breastfeeding (p-value = 4.71e-121), menopause/hysterectomy status (p-value = 6.14e-148), and iron deficiency (p-value = 9.24e-322). Contingency tables are provided to show the significance, as reflected in the negative log10 transformation of the FDR-adjusted p-value from the regression analysis for that chemical biomarker. As shown in Fig. 3A, non-Hispanic Black, Mexican American, Other Hispanic, and other race/multiracial women had the highest levels of cotinine, a smoking biomarker, relative to non-Hispanic White women. Conversely, the smoking biomarker, NNAL, was significantly lower in Other Hispanic women. Fig. 3D also shows the distinct exposure pattern in women of other race/ethnicity or multiracial women. Here, levels of heavy metals, including cadmium, mercury, and multiple arsenic biomarkers, are significantly elevated relative to non-Hispanic White women. Conversely, the smoking biomarkers, NNAL and cotinine, are significantly lower in Other Hispanic women. Fig. 3D also shows that either exposure differences between races for these chemicals are mediated by PIR, and/or exposure differences are explained by interactions between race and socioeconomic status. To visualize differences in chemical biomarker concentrations by race across a gradient of income for a few selected biomarkers, we generated violin plots of the chemical biomarker distribution stratified by categories of PIR for each race/ethnicity (Fig. S2). For benzophenone-3 and cotinine (Fig. S2A and S2B), the trends of biomarker concentrations across the PIR categories and the average concentrations within the same PIR categories differ by race. This is similar for ethylparaben (Fig. S2C), but differences are not as drastic. On the other hand, mercury (Fig. S2D) along with other remaining chemicals demonstrated a very different pattern from those of the previously mentioned substances. Across all races, the trends across PIR categories are similar for mercury, but within the same PIR category, there are differences in biomarker concentrations by race, suggesting that many chemical exposures disparities by race are independent of PIR. We also characterized how reproductive and nutritional factors such as parity, breastfeeding, menopause/hysterectomy status, and iron deficiency may influence racial disparities in chemical exposures, as well as to account for racial variations in these factors in our models (Aliyu et al., 2005; Henderson et al., 2008; Zakai et al., 2008). There are significant differences by race in all studied reproductive and nutritional factors with the p-values listed as the following: parity (p-value = 6.59e-95), breastfeeding (p-value = 4.71e-121), menopause/hysterectomy status (p-value = 6.14e-148), and iron deficiency (p-value = 9.24e-322). Contingency tables are provided to show the
frequency distribution of these variables by race in Excel Tables S10–13. In addition, we compared how differences in chemical biomarker concentrations by race/ethnicity change with and without accounting for these factors by generating a series of correlation plots comparing regression coefficients from models that include or exclude these factors (Fig. S3–S6 and Excel Tables S14–S17). Full regression results are tabulated in Excel Tables S18–S21 for all regression models that adjusted for these factors. Adjusting for either iron deficiency or menopause/hysterectomy status resulted in four chemicals that have the relative differences changed by greater than 25%, implying that neither iron deficiency nor menopause are primary driver in explaining racial differences in exposure. On the other hand, adjusting for breastfeeding and parity showed 25 and 16 chemicals, respectively, with changes greater than 25%, which implies that racial disparities in chemical exposure are better explained by these factors. For cotinine, the changes in relative differences by race were among the highest, at approximately two fold, when either menopause or breastfeeding was considered in the regression models.

Starting in 2011, more detailed information on NHANES study participant race/ethnicity were collected, including specifically identifying individuals who report Asian ethnicity. To understand whether the results presented in Fig. 3D predominantly reflect results in Asian
women, who prior to 2011 were categorized in other race/multi-racial category, we assessed exposure disparities specifically in the Asian population. These results, presented in Fig. 4A, show that, on average, multiple heavy metal biomarkers are more than 2-fold higher relative to non-Hispanic White women, including cadmium, mercury, lead, and arsenics. Additionally, the PFAS compound PFDA is significantly higher in Asian women, while cotinine and biomarkers of phosphate flame retardants (Bis(1,3-dichloro-2-propyl) phosphate, Dibutyl phosphate, Diphenyl phosphate) are significantly lower. We also calculated whether there were significant disparities in chemical biomarker concentrations in women of other or multi-race after excluding Asian women. Fig. 4B suggests relatively few differences in this regard, confirming that the other race effect in Fig. 3D is indeed associated with Asian women. Full regression results across all covariates for the 2011–2014 data are presented in Excel Table S22.

We have previously shown dramatic differences in the chemical “exposome” by age in NHANES study participants, not stratified by gender or race (Nguyen et al., 2019). Here, we tested for differences in chemical biomarkers by race, after stratifying by age group. Fig. 5 displays these results across the entire study population from 1999 to 2014. Excel Tables S23–S26 include the results for all regression analyses stratified across each of the four age groups. Blue colors reflect chemicals where levels are higher in non-Hispanic White women, while red colors reflect chemicals that are of higher concentration in women of the labeled race/ethnicity. Here, there appear to be exposure disparity patterns that persist across age groups – such as higher 2,4- and 2,5-dichlorophenol concentrations in Mexican American, Other Hispanic, and non-Hispanic black women. Differences in 1,4-dichlorobenzene concentrations are consistent across age groups, although this biomarker was not measured in the youngest individuals. Heavy metal concentrations are elevated in women of other race across age groups. Some exposure patterns differ by age, however. For example, differences in methyl and propyl paraben are most apparent between young non-Hispanic black and non-Hispanic White women less...
than 12 years old. Increased levels of phosphate flame retardants and the insect repellent DEET in non-Hispanic White women are the most evident in women less than 12 years of age. Reduced levels of brominated flame retardants (PBDE’s) in non-Hispanic White women are emphasized for adolescents, age 12–19 (all other races are higher, in red). Similarly, higher relative concentrations of benzophenone-3, bisphenol A, and bisphenol F occur in non-Hispanic White women less than 12. Elevated PCB levels in non-Hispanic black women shown in Fig. 3A are most evident in women greater than 51 years of age. Overall, these results highlight racial exposure disparities that are either stable or that vary across age groups.

To characterize how racial disparities in chemical exposures changes over time, we conducted analyses stratified by NHANES cycles. These results are display in Fig. 6 and tabulated in Excel Table S27. There are exposure disparities patterns that persist across time for arsenics and its metabolites, chemicals used in personal care products, cotinine, 2,5-dichlorophenol, 2,4-dichlorophenol, and 1,4-dichlorobenzene. Differences in 2,5-dichlorophenol concentrations are consistent higher in Non-Hispanic Black women over time, while differences peaked at the turn of the century and towards the end of 2000s, respectively, for Mexican American and Other Hispanic women. Arsenic and its metabolite arselenobetaine show the highest disparities in Other Race/Multi-Racial women with the disparities peaking in 2007–2010. Disparities patterns for methyl and propyl parabenls fluctuate over time in Mexican American, Other Hispanic, and Non-Hispanic Black women, while differences for these substances are slightly increasing in Other Race/Multi-Racial women. For mono-ethyl phthalate, a metabolite of DEP used in personal care products, differences over time are consistent in Mexican Americans, fluctuating in Other Hispanics, and increasing in non-Hispanic Black women. Differences in cotinine levels are among the highest in Non-Hispanic White women compared to Mexican American and Other Hispanic women with disparities plateauing and increasing, respectively.

4. Discussion

Based on population based chemical biomonitoring generated as part of the 1999–2014 NHANES, we performed a comprehensive analysis of racial disparities in biomarker concentrations of 143 chemicals in 38,080 participants. Specifically, we quantified the relative magnitude of racial disparities for individual chemicals and chemical families while utilizing appropriate regression weightings. This helped ensure that the results were as generalizable to the entire US population. These results highlighted striking differences in chemical biomarker exposure patterns by race/ethnicity, independent of other demographic factors such as socioeconomic status and independent factors such as menopause/hysterectomy status, parity, breastfeeding, and iron deficiency. In particular, exposure patterns of pesticides, heavy metals, tobacco smoke associated compounds, and chemicals found in personal care products are found to be most disparate across race/ethnic groups. Stratified analyses revealed exposure patterns that persisted across age groups. For example, this was apparent in heavy metals exposure for women who identify as other race or multiracial, as well as in age-specific exposure patterns, such as elevated PCB, dioxin, and dibenzofuran exposure in older non-Hispanic black women. In some cases, average differences in chemical biomarker concentrations between race/ethnic groups exceeded 400%, such as for urinary propyl or methylparaben concentrations between the youngest non-Hispanic Black and non-Hispanic White women. Racial disparities were attenuated or emphasized after adjusting for reproductive and nutritional factors. For example, when adjusting for breastfeeding, the average differences in cotinine biomarker levels were attenuated two-fold between Hispanic and non-Hispanic White women, whereas accounting for variation in iron deficiency resulted in average differences in cotinine levels increasing by two-fold when comparing between non-Hispanic Whites and non-Hispanic Black women. Since parity, breastfeeding, menopause, and iron deficiency may influence the absorption or elimination of chemicals, and the rates of these potential confounders differ by race, these factors may lead to further attenuation or amplification of racial disparities in chemical biomarker concentrations. These findings contextualize racial disparities in chemical exposures across US women and highlight the vast differences in chemical exposomes between demographic groups with well characterized disparities in health outcomes.

Environmental injustice is the disproportionate exposure of individuals of color, lower socioeconomic status, or other politically disadvantaged groups to toxic chemicals in food, air, consumer products, at the workplace, or in their communities (Brulle and Pellow, 2005). Disproportionate chemical exposures have been hypothesized to

Color reflects the log2 fold difference in chemical biomarker concentration. Biomarkers in grey color were not measured in that age group.
be important drivers of health disparities, including obesity and neu-
rodevelopmental outcomes (Landrigan et al., 2010). While the primary
goal of this study was to quantify and compare chemical exposure
disparities across racial/ethnic groups, independent of income, others
have evaluated combined income and race related disparities in ex-
posure. For instance, one analysis compared geometric mean
concentrations of 228 chemical biomarkers between six groups strat-
ified by income and race in NHANES and identified 37 chemicals as
likely contributing to environmental justice (Belova et al., 2013). Some
of these chemicals, including cotinine, lead, 2,4- and 2,5-di-
chlorophenol, methyl paraben, and propyl paraben, were associated
with the highest disparities across race/ethnic group in the present

study. We also compared chemical exposures disparities across racial/ethnic groups with and without adjustment for income and found that cotinine, PCB 194, methyl mercury, and chemicals used in personal care products such as benzophenone-3, the parabens, and triclosan show disparities across both race and socioeconomic status. However, for most of the studied chemicals, differences in chemical exposures were not driven by socioeconomic status but were instead primarily associated with race/ethnicity. Furthermore, a study of racial and social disparities in exposure to BPA and PFAS examined differences in biomarker concentrations in NHANES study participants (Nelson et al., 2012). The concentrations of the four PFAS chemicals examined, PFOS, PFPeA, PFHxS, and PFHxS, were inversely associated with household income, while BPA concentrations were higher in individuals who reported low food security (Nelson et al., 2012). Here, we identified that, independent of socioeconomic status, as assessed by poverty-income ratio, non-Hispanic White women had the highest concentrations of PFOS, while non-Hispanic Black and other race/multiracial women had the highest concentrations of PFDA. Major routes of exposure to PFAS compounds include contaminated drinking water (Hu et al., 2016), diet (Schechter et al., 2010), and occupational routes (Laitinen et al., 2014). BPA concentrations were not strikingly different by race in our study, but non-Hispanic Black women had, on average, 93% higher BPS concentrations than non-Hispanic White women. Common routes of exposure to BPA and other bisphenol analogues are diet, thermal paper, and personal care products (Chen et al., 2016). Further research is necessary to identify the major routes of exposure which are driving racial disparities in PFAS and bisphenol chemicals biomarker concentrations.

The findings of highly elevated monoethyl phthalate and methyl and propyl paraben concentrations in the non-Hispanic Black women are consistent with a personal care product route of exposure. A study assessing the chemical composition of hair products used by Black women consistently identified high levels of cyclosiloxanes, parabens, and the fragrance carrier diethyl phthalate (Helm et al., 2018). In our study, the concentrations of the diethyl phthalate metabolite monoethyl phthalate were approximately 78% higher on average in non-Hispanic black women of all ages relative to non-Hispanic White women, and 122% higher in non-Hispanic black women less than 12 years of age. This is concerning, since urinary concentrations of monoethyl phthalate have been positively associated with odds of developing breast cancer in a case-control study of women from Northern Mexico (López-Carrillo et al., 2010). Differences in concentrations of methyl and propyl paraben biomarkers were among the highest observed in this study, particularly for the youngest non-Hispanic Black women. These differences were observed to remain consistently higher across the NHANES cycles in Mexican Americans, Other Hispanics, and non-Hispanic Blacks. These chemicals have been used as preservatives in personal care products, pharmaceuticals, and food additives, and have been found to promote cell growth through multiple mechanisms, including estrogenicity (Gonzalez et al., 2018, 2019; Okubo et al., 2001) and epidermal growth factor receptor signaling (Pan et al., 2016). Particularly relevant to our findings of the greatest methyl and ethyl paraben disparities in the youngest non-Hispanic Black women was the finding that early life paraben exposures can alter developing mammary gland morphology and induce gene expression that resembles an early cancer-like state (Gopalakrishnan et al., 2017). Use of hair products has been identified as a potential risk factor for breast cancer in non-Hispanic Black women (Stiel et al., 2016; Eberle et al., 2019). When we adjusted for breastfeeding in the regression models, parabens levels are higher in Non-Hispanic White women compared to Mexican American, Other Hispanics, and Other Race/Multi-Racial women. This implies that women of other races are breastfeeding more often (Singh et al., 2007), and/or they are eliminating parabens from their body but exposing their infants via breast milk (Hines et al., 2015). Further research is needed to determine whether early-life exposure to potentially estrogenic compounds, like parabens, can induce biological alterations that increase risk of estrogen receptor negative breast cancers.

One of the most apparent disparities in chemical biomarker concentrations by race was with the compounds 2,4-dichlorophenol, 2,5-dichlorophenol, and 1,4-dichlorobenzene. 1,4-dichlorobenzene is used as a disinfectant, pesticide, and deodorant. 2,5-dichlorophenol is a metabolite of 1,4-dichlorobenzene, while 2,4-dichlorophenol is a metabolite of the antimicrobial triclosan or other pesticides. Elevated concentrations of these chemicals in non-Hispanic Black individuals have been noted previously (Belova et al., 2013; Ye et al., 2014) The concentrations of these three chemicals were up to 350% higher on average in non-Hispanic Black women, relative to non-Hispanic White women, and also elevated in Mexican American and Other Hispanic women. Importantly, these exposure disparities were consistent across all age groups. While 2,4-dichlorophenol concentrations were significantly elevated in non-Hispanic Black and Hispanic women, urinary triclosan levels were not significantly different by race/ethnicity. This suggests that either triclosan is not the main chemical exposure that explains the differences in concentrations of 2,4-dichlorophenol or that there are differences in metabolism and excretion rates by race, which is less likely. 2,5-dichlorophenol is of particular interest, since after adjusting for breastfeeding, the exposure disparity between Mexican American and non-Hispanic White women was further emphasized. In a study measuring environmental phenols in milk of lactating North Carolina women, 2,5-dichlorophenol was undetectable in all milk samples (Hines et al., 2015). This suggests that either 2,5-dichlorophenol is not absorbed into breast milk, or it is hindering lactation and therefore excretion through this pathway. 1,4-dichlorobenzene exposure has been associated with altered thyroid biomarkers in NHANES (Wei and Zhu, 2016), altered immunologic and liver function parameters in occupationally exposed workers (Hsiao et al., 2009), and altered sperm production and increased prostate weight in exposed rats (Takahashi et al., 2011). Understanding and mitigating exposure to these chemicals is therefore of importance to reduce disparate risk of these health outcomes.

Heavy metals were among the chemicals most consistently different across racial/ethnic groups. In particular, women who identified as other race or multiracial had the highest concentrations of multiple metals, including cadmium, mercury, arsenics, lead, and manganese. Focusing on data from NHANES 2011–14, we identified that these elevated metal concentrations were restricted to women who identified as Asian. This is consistent with a previous finding of increased concentrations of a subset of these metals in Asian NHANES participants (Awata et al., 2017). Furthermore, elevated levels of mercury, lead, and arsenics were also identified in non-Hispanic Black women, relative to non-Hispanic White women. Mexican American women had elevated levels of uranium, lead, mercury, arsenics, and cadmium, while Other Hispanic women had higher concentrations of mercury, arsenics, and cadmium than non-Hispanic White women. Non-Hispanic White women, however, had higher concentrations of urinary barium. In our temporal analysis, differences in biomarker levels between Other Race/Multi-Racial and Non-Hispanic White women are increasing for cadmium, mercury, and dimethylarsenic acid. While studies have identified the interaction between iron deficiency and biomarker levels of heavy metals (Hegazy et al., 2010; Kwong et al., 2004), we observed in our study that accounting for iron deficiency in the regression models did not influence the racial disparities for heavy metals. Previous research has linked diet, occupation, education level, and smoking status to elevated metals exposure (Awata et al., 2017), in addition to housing (Jacobs et al., 2013), air pollution (Suvarapu and Baek, 2016), and contaminated water (Pieper et al., 2017). The well characterized toxicity of heavy metals exposure, even at low doses, makes identifying and ameliorating heavy metal exposures a top priority for addressing environmental health disparities.

The oldest non-Hispanic Black women in our study had consistently higher concentrations of persistent organic pollutants, including dioxins, dibenzofurans, PCBs, and DDT metabolites. In addition, these
stark disparities for the persistent organic pollutants were plateauing or increasing over time in non-Hispanic Black women when these chemicals were last measured in NHANES. This is consistent with a previous report of non-Hispanic Black individuals having an increased risk of having multiple persistent organic pollutants detectable their blood (Pumareaga et al., 2016) or higher average levels of PCBs (Xue et al., 2014). In our study, biomarker levels of most PCBs were higher in women who were iron deficient. The less persistent PCBs were also of lower concentrations in women who breastfed or have higher parity, suggesting that the depuration of PCBs occurs through these excretion mechanisms (Alcala and Phillips, 2017; Aliyu et al., 2005). However, biomarker levels were shown to be higher for the more persistent PCBs. Biomarkers of persistent organic pollutants were quantified on an individual (non-pooled) basis in the 1999–2004 NHANES cycles. Elevated concentrations of these pollutant, such as the DDT metabolite, DDE, have been associated with an increased risk of breast cancer (Wolff et al., 1993). Interestingly, racial differences in DDE further increased when either parity or breastfeeding was accounted in the regression models, suggesting that environmental insult from this substance may perturb pathways associated with the reproductive system. A lack of disparities, and decreasing concentrations of these chemicals in younger individuals over time, generally reflect a public health success in decreasing population exposures to these toxic compounds (Nguyen et al., 2019). The long half-life of these chemicals suggests that the detected biomarkers predominantly reflect historical exposures. This could, however, be of substantial importance for children of non-Hispanic Black women, who could have been exposed to disproportionately high levels of these chemicals in the womb or early in childhood. For example, in utero exposure to the pesticide, DDT, has been associated with an increased risk of breast cancer in adulthood. Specifically, women in the highest quartile of in utero DDT exposure were found to have a 3.7-fold increased risk of developing breast cancer relative to women in the lowest quartile of exposure (Cohn et al., 2015). Prenatal exposure to organochlorine compounds has also been associated with decreased lung function later in life (Hansen et al., 2016), risk of infection in childhood (Dewaally et al., 2000), attention deficit hyperactivity disorder (Sagiv et al., 2010), and obesity (Mendez et al., 2011). If these effects of elevated early life persistent organic pollutant exposure last throughout the life course, there could be continued adverse health consequences that manifest in those exposed for the foreseeable future.

Our study has important limitations. First, the cross-sectional nature of NHANES only allows biomarker measurement at one time point per individual. In addition, there are no available data on season, but should such data become available, then it would be interesting to study chemical exposure trends across the seasons. Moreover, since the half-lives of the biomarkers assessed in this study are highly variable (Nguyen et al., 2019), the precision of estimates of long-term exposure largely varies across chemical family. Additionally, this study was not able to assess geographic variation in exposure. Others have identified that persistent organic pollutant exposures in the NHANES cohort varies geographically, with higher DDT metabolite concentrations in individuals residing in the West, and elevated PCB concentrations in individuals residing in the Northeast (Wattigney et al., 2015). Future work is needed to precisely characterize exposure “hot spots,” in order to design intervention studies to reduce exposure disparities. Our study also focused on identifying average differences in biomarker concentrations. By ignoring the extremes of these distributions, we have likely not considered individuals at greatest risk of developing adverse health outcomes. Similarly, our analyses were limited by low detection rates, with 182 chemicals not meeting our inclusion threshold of at least 50% detection in the study population. A more in-depth analysis of differences in detection frequency by race/ethnicity could identify additional chemicals with significant racial disparities. For chemical biomarkers measured in urine, variation in the concentration of urinary creatinine, used as a correction factor for urine dilution, potentially confounds our comparison of exposures between individuals of different races. This is because increased average concentrations of urinary creatinine have been identified for non-Hispanic Black individuals, relative to Mexican American and non-Hispanic White individuals (Barr et al., 2005). While we adjusted for urinary creatinine as a covariate in our regression models, there still may be residual confounding. The large number of chemicals assessed also precluded an in-depth characterization of the various routes of exposure of individual chemicals – this is undoubtedly an essential future direction of research to develop strategies to eliminate exposure disparities. Finally, while we performed analyses of all chemical biomarkers available from NHANES 1999–2014, these chemicals only represent a small proportion of the over 80,000 chemicals estimated to be used in commerce in the United States. Future studies could benefit from an unbiased metabolomics approach to identify disparities in chemical exposures which are not captured in NHANES.

The persistent health disparities between women of different races/ethnicities make understanding the etiological drivers of these disparities a pressing public health issue. A recent commentary highlighted a lack of knowledge regarding the molecular underpinnings of health disparities. It described how the vast majority of genome sequencing data had been generated in populations of European ancestry (Sirugo et al., 2019). Environmental exposures, however, are hypothesized to be the major driving risk factors for a vast suite of complex diseases (Rappaport and Smith, 2010). Even when genetic data has been generated in an equitable fashion, understanding gene-environment interactions and complex disease phenotypes will still require in-depth quantification of environmental exposures. In this study, we have comprehensively identified differences in biomarker of chemical exposure across women of various race/ethnic groups and across age groups. These findings can guide future efforts to understand chemical impacts on health disparities by helping to prioritize chemicals for assessment in epidemiological studies. Additionally, chemicals as identified as highly disparate here can be further prioritized for toxicological assessment relevant to disease outcomes of interest. Finally, these findings can inform public health interventions designed to reduce chemical disparities and promote health equity across the population.
