INTRODUCTION: Barrier tissues are constitutive targets of environmental stressors and are home to a highly diverse microbiota. When the immune system encounters these noninvasive microbes, one possible result is the induction of cognate T cell responses that control various aspects of tissue function, including antimicrobial defense and tissue repair. Given the extraordinary number of antigens expressed by the microbiota, a substantial fraction of barrier tissue-resident T cells are expected to be commensal-specific, accumulating over time in response to successive exposure to new commensals. Because barrier tissues are defined by the constitutive coexistence of commensals and commensal-reactive lymphocytes, any understanding of tissue homeostasis, response to injury, and tissue-specific pathologies must occur in the context of this fundamental dialog.

RATIONALE: The skin serves as a primary interface with the environment and is consequently a constitutive target of environmental stressors mediated by physical damage or invasive pathogens. Tissue protection from these

challenges relies on rapid and coordinated local responses tailored to both the microenvironment and the nature of the instigating injury. Our study explored whether commensal-specific T cells can act as tissue sentinels, allowing rapid adaptation to defined injuries, and how dysregulation of these responses may have pathogenic consequences.

RESULTS: Homeostatic encounters with commensal microbes promoted the induction of commensal-specific interleukin-17A (IL-17A)-producing T cells [CD4⁺ (T_{H17}) and CD8⁺ (T_{C17})] that persisted as tissue-resident memory cells. Surprisingly, commensal-specific T cells were characterized by coexpression of classically antagonistic transcription factors (ROR γ t and GATA-3) that control the respective expression of type 17 and type 2 programs. Consequently, commensal-specific T cells displayed a hybrid chromatin landscape that underlies the co-expression of a broad type 2 transcriptome, including the type 2 effector cytokines IL-5 and IL-13. Notably, during homeostasis, ROR γ t⁺ T cells expressed type 2 cytokine mRNA without subsequent protein translation. By contrast, in

the context of tissue challenges such as chitin injection or insect bites, commensal-specific ROR γ t⁺ T cells were able to produce type 2 cytokines (IL-5 and IL-13). The spontaneous release of type 2 cytokines by these cells was also observed in the context of local defects in immune regulation associated with impaired regulatory T cell function. Alarms associated with tissue damage and inflammation, such as IL-1, IL-18, IL-25, and IL-33, were able to superimpose a type 2 effector program on both T_{C17} and T_{H17} cells in the context of T cell receptor engagement. Using an IL-17A fate-mapping strategy, we found that IL-17A-committed ROR γ t⁺ T cells and their IL-17A-

ROR γ t⁺ counterparts both produced type 2 cytokines in response to tissue alarms. Such cellular plasticity allows commensal-specific type 17 cells to promote IL-17A-mediated antimicrobial defense under homeostatic conditions, as well as tissue repair in an IL-13-dependent manner in the context of tissue injury.

CONCLUSION: Our work describes a tissue checkpoint that relies on the remarkable plasticity and adaptability of tissue-resident commensal-specific T cells. We propose that this feature may also have important implications in the etiology of tissue-specific inflammatory disorders. The extraordinary number of both commensal-derived antigens and T cells at barrier sites suggests that the ability of commensal-specific T cells to functionally adapt to injury may play a fundamental role in controlling tissue physiology. ■

Poised type 2 immunity of commensal-specific T cells promotes rapid adaptation to tissue injury. Commensal-specific T cells produce IL-17A under homeostatic conditions for antimicrobial defense while harboring a poised type 2 transcriptome. Tissue injury licenses type 2 immune potential of commensal-specific type 17 T cells, thereby promoting tissue repair. Impaired immune regulation unleashes type 2 cytokine production from commensal-specific CD8⁺ T_{C17} cells.

Barrier tissues are primary targets of environmental stressors and are home to the largest number of antigen-experienced lymphocytes in the body, including commensal-specific T cells. We found that skin-resident commensal-specific T cells harbor a paradoxical program characterized by a type 17 program associated with a poised type 2 state. Thus, in the context of injury and exposure to inflammatory mediators such as interleukin-18, these cells rapidly release type 2 cytokines, thereby acquiring contextual functions. Such acquisition of a type 2 effector program promotes tissue repair. Aberrant type 2 responses can also be unleashed in the context of local defects in immunoregulation. Thus, commensal-specific T cells co-opt tissue residency and cell-intrinsic flexibility as a means to promote both local immunity and tissue adaptation to injury.

BARRIER tissues are constitutive targets of environmental stressors as well as primary sites of exposure to symbiotic and pathogenic microbes. As such, under homeostasis, barrier tissues are home to vast numbers of antigen-experienced lymphocytes. The numerous and diverse microbes that colonize these tissues, referred to as the microbiota, play a fundamental role in the induction and quality of these local immune responses, including those that are directed at the microbiota itself (1–4). Indeed, far from being ignored, microbes at all barrier surfaces are actively recognized by the immune system. Encounters with noninvasive symbionts can lead to the induction of cognate

T cell responses (1–4). This tonic recognition promotes a highly physiological form of adaptive immunity that can control distinct aspects of tissue function, including antimicrobial defense and tissue repair (5, 6). Because of the extraordinary number of antigens expressed by the microbiota, a substantial fraction of barrier tissue-resident T cells are expected to be commensal-specific, accumulating over time in response to successive exposure to new commensals. This understanding of host-microbiota interactions has important implications for our understanding of host immunity and pathologies. Because barrier tissues are defined by the constitutive coexistence of commensals (and associated antigens) and commensal-reactive lymphocytes, our understanding of tissue homeostasis, response to injury, and tissue-specific pathologies must occur in the context of this fundamental dialog.

The skin serves as a primary interface with the environment and is consequently a constitutive target of environmental stressors mediated by physical damage, invasive pathogens, impaired immune regulation, or the nutritional state of the host. Tissue protection from these challenges relies on rapid and coordinated local responses tailored to both the microenvironment and the nature of the instigating injury. Recently, the discovery that cells such as innate lymphoid cells (ILCs) can rapidly respond to mediators released during tissue damage has provided a framework to begin to understand this phenomenon. Whether tissue-resident T cells, particularly those specific to commensals, can also act as tissue sentinels allowing rapid adaptation to

defined injury remains unknown. Here, we explored the unique features of commensal-specific T cells and how their distinct wiring might promote physiological or pathological tissue adaptation.

Acute injury licenses type 2 cytokine production from commensal-specific type 17 T cells

The skin is home to a number of resident lymphocytes, some of which recognize the microbiota (4, 6–8). We first assessed whether commensal-specific T cells could develop as nonrecirculating tissue-resident memory cells (T_{RM}), a subset of memory T cells previously shown to accumulate in tissues upon pathogen encounter and promote local immunity (9). *Staphylococcus epidermidis* colonization of the skin promotes the noninflammatory accumulation of both CD4⁺ [T helper 1 ($T_{H}1$) and $T_{H}17$] and CD8⁺ T cells [T cytotoxic 1 ($T_{C}1$) and $T_{C}17$] (4). A large fraction (>80%) of these *S. epidermidis*-specific polyclonal CD8⁺ T cells are nonclassically restricted (6). *S. epidermidis*-specific CD8⁺ T cells can be tracked via the use of a peptide-major histocompatibility complex (MHC) tetramer (f-MIIINA: H2-M3) (6) and newly generated T cell receptor (TCR)-transgenic mice (Bowie^{Tg}). Both tools recapitulate the *S. epidermidis*-specific polyclonal CD8⁺ T cell response, including cytokine potential, skin-homing, and distribution of the tissue residency markers CD69 and CD103 (9) (Fig. 1, A to C). To assess tissue residency, we generated *S. epidermidis*-colonized parabiotic mice, which establish chimerism through joint circulation (10) (fig. S1A). In contrast to lymphoid organs, where cells equilibrated, f-MIIINA:H2-M3⁺ CD8⁺ T cells within the skin were host-derived (97.1 ± 2.4%) and coexpressed CD103 and CD69 (Fig. 1, D and E). Thus, commensal-specific T cells can develop as long-lived tissue-resident memory T cells.

Given the fundamental role of the skin as a protective barrier, we sought to determine the impact of environmental stressors on commensal-specific tissue-resident T cells. After colonization, *S. epidermidis*-specific polyclonal CD8⁺ T cells were identified as T-bet⁺CCR6[−] $T_{C}1$ cells or ROR γ t⁺CCR6⁺ $T_{C}17$ cells [of which ~30% have interleukin (IL)-17A production potential] (Fig. 1, F and G). Although the intradermal injection of chitin or sand fly (*Lutzomyia longipalpis*) bites had no impact on the potential for IL-17A and interferon (IFN)- γ production by $T_{C}17$ and $T_{C}1$ cells, respectively (Fig. 1H), both stressors revealed a surprising potential for the production of IL-5 and IL-13 from *S. epidermidis*-elicited $T_{C}17$ cells, including f-MIIINA:H2-M3⁺ CD8⁺ T cells (Fig. 1, H and I, and fig. S1, B and C). Increased type 2 cytokine production after chitin or sand fly challenge was also observed from ROR γ t-expressing CD4⁺ T cells ($T_{H}17$) elicited by *S. epidermidis* (fig. S1D). Thus, ROR γ t⁺ T cells (both CD8⁺ and CD4⁺ T cells) elicited by encounter with a commensal may have the unexpected potential to produce type 2 cytokines in response to defined tissue challenges.

Local defects in immunoregulation unleash type 2 immunity from commensal-specific T cells

Flow cytometric analysis revealed that T_c17 cells coexpressed GATA-3, the lineage-defining transcription factor (LDTF) for both T_H2 cells and group 2 ILC (ILC2) (Fig. 2A). Such a phenotype was also detected among the very few CD8⁺ T cells present in the skin of naïve mice (fig. S2A), and coexpression of ROR γ t and GATA-3 by *S. epidermidis*-specific Bowie^{Tg} CD8⁺ T cells was restricted to the skin and not detectable in secondary lymphoid organs; these findings suggested that GATA-3 expression is imprinted within the tissue microenvironment (fig. S2B). This phenotype was conserved across T cell lineages and distinct microbial exposures. Notably, T_H17 cells elicited by skin colonization with *S. epidermidis* or *Candida albicans* also expressed GATA-3 (Fig. 2B and fig. S2C). Thus, homeostatic encounter with bacterial or fungal commensal microbes can lead to the development of cells with a paradoxical phenotype characterized by the coexpression of classically antagonistic transcription factors.

The skin is highly enriched in Foxp3⁺ regulatory T (T_{reg}) cells (5), and confocal imaging re-

vealed colocalization of *S. epidermidis*-induced CD8⁺ T cells and Foxp3⁺ T_{reg} cells (Fig. 2C). As such, we assessed the possibility that skin Foxp3⁺ T_{reg} cells could limit type 2 cytokine production by commensal-specific type 17 cells. Because complete ablation of Foxp3⁺ T_{reg} cells results in severe local and systemic inflammatory responses and aberrant accumulation of T_c1 cells within the skin (11) (fig. S2, D and E), we used an approach allowing for a tissue-specific defect in immunoregulation. Within the skin, T_{reg} cells express high levels of GATA-3 (but not other LDTFs) (Fig. 2D and fig. S2F), a factor that contributes to T_{reg} cell stability and fitness (12–15). In mice in which T_{reg} cells were conditionally deleted of GATA-3 (*Foxp3*^{YFP-Cre}*Gata3*^{f/f}), Foxp3⁺ cells were reduced in frequency and exhibited decreased Foxp3 and CD25 expression in the skin, but not in other tissues (Fig. 2E and fig. S2, G and H). Consistent with this observation, by 10 weeks of age, skin-draining lymph nodes (but not other lymphoid structures) were enlarged, and the skin compartments (but not other tissues) of these mice were characterized by a selective increase in the number of T cells producing IL-5 and IL-13 (Fig. 2, F and G, and fig. S2, I to K). Enhanced type 2 responses

were associated with discrete elevated frequencies and absolute numbers of eosinophils and basophils in the skin of *Foxp3*^{YFP-Cre}*Gata3*^{f/f} mice relative to control mice (Fig. 2H and fig. S2L). Of note, and in agreement with a skin-specific defect, naïve *Foxp3*^{YFP-Cre}*Gata3*^{f/f} mice, with an endogenous skin microbiota but not *S. epidermidis*, spontaneously developed severe skin inflammation (but not systemic inflammation) with ~70% penetrance by 8 months of age (Fig. 2, I and J).

To assess the possibility that T cells producing type 2 cytokines within the skin of these mice are commensal-specific, we colonized young *Foxp3*^{YFP-Cre}*Gata3*^{f/f} mice (before inflammation) and control mice with *S. epidermidis* and tracked the fate of *S. epidermidis*-specific T cells. Adoptively transferred Bowie^{Tg} CD8⁺ T cells (as well as host polyclonal *S. epidermidis*-induced CD8⁺ T cells) expressed IL-5 and IL-13 proteins in the skin of *Foxp3*^{YFP-Cre}*Gata3*^{f/f} mice but not control mice (Fig. 2, K to M). By contrast, the ability of *S. epidermidis*-elicited CD8⁺ T cells to produce IL-17A or IFN- γ was unaffected (fig. S2M). Notably, type 2 cytokine production by *S. epidermidis*-specific polyclonal and adoptively transferred Bowie^{Tg} CD8⁺ T cells remained restricted to cells

Fig. 3. *S. epidermidis*-specific Tc17 cells express a broad type 2 signature.

signature. Tc17 (CD8⁺CCR6⁺) and Tc1 (CD8⁺CCR6⁻) cells were isolated by FACS from the skin of *S. epidermidis*-colonized wild-type mice for transcriptomic and epigenetic analysis by RNA-seq and ATAC-seq. ATAC-seq signals from canonical naïve and memory CD8⁺ T cells were from lymphoid tissue. Representative transcription factor binding motifs enriched in indicated groups are listed on

the right. (B to E) Genomic tracks of ATAC-seq and RNA-seq signal profiles in Tc17 and Tc1 cells across signature cytokine genes. Genomic location of Tc17-specific regulatory elements with GATA-3 binding motifs are denoted by red triangles. (F) Heat map of lineage-specific signature genes expressed by Tc17 and Tc1 populations. (G) Chromatin accessibility at transcription start site (promoter ± 500 bp) of *II5* and *II13* in Tc17 and Tc1 cells. Bar graphs show means ± SD. Sequencing data represent two or three independent biological replicates. *P < 0.05 (Student *t* test).

Fig. 4. *S. epidermidis*-specific Tc17 cells harbor a poised type 2 transcriptome. (A) and (B) Tc1 (CD8⁺CCR6⁻), IL-17A^{FM+} Tc17 (CD8⁺CCR6⁺eYFP⁺), and IL-17A^{FM-} Tc17 (CD8⁺CCR6⁺eYFP⁻) cells were isolated by FACS from the skin of *S. epidermidis*-colonized *Il17a*^{Cre}*R26R*^{eYFP} (IL-17A^{FM}) mice and analyzed by scRNA-seq. (A) tSNE plots of scRNA-seq expression highlighting Tc1 (gray), IL-17A^{FM+} Tc17 (orange), and IL-17A^{FM-} Tc17 (blue) populations. (B) Expression of LDTFs and cytokine genes projected onto a tSNE plot. (C) Representative dot plots of cytokine protein production potential and mRNA expression by Tc17 cells from the skin of *S. epidermidis*-colonized wild-type mice. (D and E) Representative dot plots of IL-17A and IL-5 or IL-13

production potential and IL5 or IL13 mRNA expression by Tc17 cells from the skin of *S. epidermidis*-colonized wild-type mice. (F) *S. epidermidis*-colonized CreERT2*Gata3*^{f/f} mice received tamoxifen or vehicle control before cell sorting of skin Tc1 and Tc17 cells. Gene expression in the indicated populations was assessed by quantitative reverse transcription polymerase chain reaction (qRT-PCR). Numbers in representative plots indicate means ± SD. Flow cytometric data represent at least two experiments with four to six mice per group. qRT-PCR data represent three biological replicates of eight pooled mice per group. *P < 0.05, **P < 0.01 (one-way ANOVA with Holm-Šidák multiple-comparison test).

expressing CCR6; this result shows that in the context of local immune defects, type 2 cytokines can be unleashed from ROR γ t-committed T cells (Fig. 2M). Thus, impaired local immunoregulation promotes type 2 cytokine production by commensal-specific type 17 cells—a property that may predispose tissue to inflammation.

***S. epidermidis*-specific Tc17 cells harbor a poised type 2 transcriptome**

To gain insight into the transcriptional and epigenetic landscape of commensal-specific T cells under homeostatic conditions, we identified global regulatory elements shared between, and unique to, *S. epidermidis*-specific polyclonal Tc17 (CCR6⁺) and Tc1 (CCR6⁻) cells from the skin and naïve and memory CD8⁺ T cells from lymphoid

tissue (16). Regulatory elements unique to skin Tc17 or Tc1 cells were enriched in binding sites for ROR γ t, and for T-bet and Eomes, respectively (Fig. 3A), consistent with subset-specific expression of these LDTFs (Fig. 1F). Elevated chromatin accessibility and transcript abundance of the signature cytokines *Ifng*, *Il17a*, and *Il17f* also confirmed the clear distinction between Tc1 and Tc17 cell subsets (Fig. 3, B and C, and fig. S3, A and B). Among regulatory elements unique to Tc17 cells, we identified previously described GATA-3-binding sites within *Il13* and the *Rad50/T*_{H2} locus control region (17) (Fig. 3, D and E). Consequently, Tc17 cells demonstrated elevated chromatin accessibility at type 2 immune gene loci encoding *Il5* and *Il13* and expressed elevated levels of *Il5* and *Il13* mRNA transcripts

relative to Tc1 cells (Fig. 3, D to G, and fig. S3C). Furthermore, Tc17 cells expressed a broad type 2 transcriptome, including a LDTF (*Gata3*) and cytokine and chemokine receptors (*Ccr8*, *Ilrl1*, and *Il17rb*), but neither *Il4* nor *Il10* mRNA, as previously described for tissue-derived T_H2 cells (18) (Fig. 3F and fig. S3D). The type 2-associated cytokine amphiregulin (*Areg*) was detectable in both cell subsets, albeit at higher abundance in Tc17 cells (fig. S3D). As such, commensal-specific Tc17 cells express a broad type 2 transcriptome under homeostatic conditions.

Of *S. epidermidis*-induced Tc17 cells, ~30% displayed the potential for IL-17A production (Fig. 1G), supporting the idea of possible phenotypic heterogeneity. However, using cells from IL-17A fate-mapping mice (IL-17A^{FM}-*Il17a*^{Cre}*R26R*^{eYFP})

and single-cell RNA sequencing (scRNA-seq), t-distributed stochastic neighbor embedding (tSNE) projection of T_{C1}, IL-17A^{FM+} T_{C17}, and IL-17A^{FM-} T_{C17} cells demonstrated considerable transcriptional overlap between IL-17A^{FM+} and IL-17A^{FM-} T_{C17} cell fractions, with type 2 cytokine mRNA-expressing cells present in both fractions (Fig. 4, A and B, and fig. S4A). Thus, commensal-specific T_{C17} cells, including those already committed to IL-17A production, can be superimposed with the expression of a type 2 transcriptome. Furthermore, *in situ* hybridization for mRNA detection by flow cytometry revealed that *Il5* and *Il13* transcripts, but not protein, were expressed selectively by T_{C17} cells from the skin of *S. epidermidis*-colonized mice (Fig. 4C and fig. S4B). In line with our scRNA-seq data (Fig. 4B and fig. S4A), *Il5*⁺ and *Il13*⁺ cells were found within both IL-17A-producing and IL-17A-nonproducing fractions of T_{C17} cells (Fig. 4, D and E); this suggests that during homeostasis, commensal-specific T_{C17} cells express type 2 cytokine mRNA without subsequent protein translation. The inducible deletion of *Gata3* at the peak of the CD8⁺ T cell response to *S. epidermidis* revealed that sustained GATA-3 expression by T_{C17} cells was required for the constitutive expression of *Il5* and *Il13*, but, as expected, not for *Il17a* (Fig. 4F). Thus, *S. epidermidis*-specific T_{C17} cells express a poised type 2 transcriptome dependent on continued GATA-3 expression.

Accordingly, type 2 cytokine competency (mRNA expression) and licensing (stimuli-induced protein production) are temporally decoupled in *S. epidermidis*-elicited T_{C17} cells—a process likely involving the posttranscriptional regulation of cytokine mRNA stability and protein translation. Under inflammatory conditions, previous work revealed that distinct stimuli can govern competency and licensing of type 2 immunity within injured tissues, ensuring tissue-restricted effector function during pathogen infection (19). Recent findings also suggest that IFN- γ production by CD8⁺ T cells is actively regulated at the level of translation, thereby preventing chronic immune activation (20–22).

Alarms license type 2 cytokine production by commensal-specific T_{C17} cells

Our work proposes that such a phenomenon may also apply to commensal-specific T cells generated under homeostatic conditions. To identify the factors capable of licensing poised type 2 immunity from commensal-specific T cells, we used an ex vivo screening approach, stimulating T_{C17} and T_{C1} cells with cytokines and alarmins previously shown to be associated with tissue damage. Cytokine stimulation alone did not promote type 2 cytokine production by skin T cells, demonstrating that these cells cannot be licensed in a TCR-independent manner (fig. S5A). Because commensal microbes persist within the skin, this result is consistent with the expectation that exposure to alarmins will occur in the context of antigen exposure. However, in line with the role of IL-1 within the skin (4),

IL-1 α significantly increased the ex vivo production of IL-17A from T_{C17} cells in the context of TCR stimulation (Fig. 5A). As previously reported, IL-18 and IL-33 promoted IFN- γ production by T_{C1} cells (23, 24) (Fig. 5B). Notably, several alarmins promoted the production of IL-5 (IL-18, IL-25, and IL-33) or IL-13 (IL-1 α , IL-1 β , IL-18, and IL-33) (Fig. 5, C and D). IL-25 potently promoted the production of IL-5 but not IL-13 (Fig. 5, C and D), supporting the idea that distinct classes of injury may have different impacts on commensal-specific T cell responses. Strikingly, IL-18, a cytokine widely linked to the initiation of type 1 responses, was particularly potent at eliciting the release of both IL-5 and IL-13 from T_{C17} cells ex vivo (Fig. 5, C and D). IL-18 also promoted IL-17A production by T_{C17} cells, further supporting the idea that this alarmin can superimpose type 2 responses upon a precommitted type 17 program (Fig. 5A). Under these conditions, IL-4 and IL-10 were undetectable (fig. S5B), but both T_{C1} and T_{C17} cells produced amphiregulin upon TCR stimulation, a response that was also enhanced by IL-18 (fig. S5C). Type 2 responses to IL-18 were not restricted to CD8⁺ T cells nor to *S. epidermidis*-elicited cells. Indeed, skin CD4⁺ T cells induced by *S. epidermidis* or *C. albicans* colonization (including T_{H17} cells) also produced higher levels of IL-5 and IL-13 upon IL-18 and TCR stimulation *in vitro* (fig. S5, D to F). Thus, such poised type 2 potential may be the norm for type 17 commensal-specific T cells raised under homeostatic conditions. In this context, local inflammatory factors including IL-1, IL-18, IL-25, and IL-33 can superimpose a type 2 effector program.

To assess the impact of a single defined alarmin on commensal-specific T cells, we next focused on the impact of IL-18 *in vivo*. A single injection of IL-18 licensed both IL-5 and IL-13 protein production by *S. epidermidis*-elicited T_{C17} (including f-MIIINA:H2-M3⁺ cells) and CD4⁺ T cells (including T_{H17} cells) (Fig. 5, E to G, and fig. S5, G and H). Type 2 cytokine licensing by IL-18 occurred at the expense of IL-17A production, suggesting dynamic regulation of cytokine production by commensal-specific T_{C17} and T_{H17} cells *in vivo* (Fig. 5, E to G). The ability of T_{C17} and T_{H17} cells to produce type 2 cytokines in response to IL-18 was dependent on T cell-intrinsic IL-18R1 signaling (Fig. 5, H and I) and was sustained up to 60 days after colonization (fig. S5I). After chitin injection, type 2 licensing of T_{C17} and T_{H17} cells was also IL-18R1 signaling-dependent (Fig. 5, H and I); these findings support the idea that in defined inflammatory settings, IL-18 alone may be sufficient to impose this response.

Commensal-specific T cell plasticity and IL-13 production promote wound repair

The co-production of cytokines associated with distinct T cell subsets can occur during inflammation. For example, IL-17A⁺IFN- γ ⁺ cells are present during intestinal and central nervous system inflammation, and IL-17A⁺IL-4⁺ cells

are found during allergic asthma and helminth infection (25–29). Previous studies also demonstrated plasticity of effector T_{H17} cells to convert to T_{H1}, follicular helper (T_{FH}), and T_{reg} cell phenotypes in a context-dependent manner (26, 30, 31). Our work supports the idea that such plasticity may be a fundamental feature of tissue-resident commensal-specific T cells. To specifically address this point, we used IL-17A^{FM} mice to assess *in vivo* the heritage of T_{C17} cells licensed for type 2 cytokine production. In line with the finding that both IL-17A^{FM+} and IL-17A^{FM-} T_{C17} cells display poised *Il5* and *Il13* mRNA expression (Fig. 4, B to E), IL-18 triggered type 2 cytokine production from both T_{C17} and T_{H17} cells regardless of whether they had previously expressed IL-17A (IL-17A^{FM+} and IL-17A^{FM-}) (Fig. 6, A and B). Thus, within commensal-induced T_{C17} and T_{H17} cell populations, plasticity among IL-17A^{FM+} cells and local licensing of IL-17A^{FM-} cells both contribute to alarmin-mediated induction of type 2 cytokine production.

Although a few reports have suggested that IL-18 can potentially promote type 2 and regulatory responses (32–34), this cytokine is more widely considered to promote type 1 immunity. In support of a major role for IL-18 in the promotion of skin type 2 responses, IL-18 injection promoted type 2 cytokine production not only by T cells but also by ILC2, as recently described (Fig. 6C) (35). In contrast to transient ILC2 responses, induction of type 2 cytokine expression by T cells was sustained up to 4 days after injection (Fig. 6C). Thus, type 2 cytokine licensing by IL-18 may have a profound effect on skin physiology via the broad impact of a defined alarmin on both tissue-resident commensal-specific T cells and ILC2 (35). Indeed, IL-18 injection promoted an IL-5-dependent eosinophil accumulation within the skin compartment of *S. epidermidis*-colonized mice (Fig. 6D and fig. S6A). Thus, tissue-resident commensal-specific type 17 T cells can adapt to defined injury by direct sensing of alarmins and inflammatory mediators.

Because of the known contribution of type 2 immunity and IL-13 in particular to tissue repair, we next used a model of skin wounding to assess the potential contribution of commensal-specific type 2 cytokine licensing to this fundamental process. Although IL-13 did not contribute to the healing process in unassociated mice, IL-13 neutralization or genetic *Il13* deficiency impaired *S. epidermidis*-accelerated wound repair (Fig. 6, E and F). Adoptive transfer of wild-type Bowie^{Tg} CD8⁺ T cells rescued this defect in an IL-13-dependent manner (Fig. 6F). In agreement with the role of IL-13 in tissue repair (36), whole-tissue RNA-seq of skin after wounding revealed an IL-13-dependent transcriptional signature dominated by pathways associated with muscle contractility and extracellular matrix reorganization (Fig. 6G and fig. S6B). Notably, in line with the fact that punch biopsies can trigger the release of numerous factors able to license type 17 cells (Fig. 5, C and D), IL-18 was insufficient

Fig. 5. Tissue alarmins license type 2 cytokine production from commensal-specific

T cells. (**A** to **D**) T_{C17} (CD8⁺CCR6⁺) and T_{C1} (CD8⁺CCR6⁻) cells were isolated from the skin of *S. epidermidis*-colonized wild-type mice and cultured in vitro with agonistic anti-CD3ε mAb and the indicated cytokines. Cell culture supernatants were assayed for cytokine production after 24 hours of culture. (**E**) Representative contour plots of IL-5 and IL-17A production potential by *S. epidermidis*-induced T_{C17} cells after i.d. injection with PBS or IL-18. (**F**) Representative contour plots of IL-5 and IL-17A production potential by skin CD4⁺Foxp3⁻ T cells from *S. epidermidis*-colonized wild-type mice after i.d. injection with PBS or IL-18. (**G**) Frequencies of T_{C17} and T_{C1} cells with indicated cytokine production potential from the skin of *S. epidermidis*-colonized wild-type mice after i.d. injection of PBS or IL-18. (**H** and **I**) Frequencies of T_{C17} (**H**) and T_{H17} (**I**) cells with indicated cytokine production potential from the skin of *S. epidermidis*-colonized *Cd4*^{Cre/+/I18r1^{fl/fl} and control mice after i.d. injection with PBS, IL-18, or chitin. Numbers in representative plots indicate means ± SD. Bar graphs show means ± SD. Data represent at least two experiments with three to six mice per group. *P < 0.05, **P < 0.01 as calculated using one-way [(A) to (D), (G)] or two-way [(H), (I)] ANOVA with Holm-Šidák multiple-comparison test.}

to promote these responses (fig. S6C). Thus, the poised type 2 immune potential of commensal-specific Tc17 cells allows for local adaptation to injury, thereby promoting tissue repair.

Conclusion

Barrier tissues are constitutively exposed to environmental stressors and are primary targets of chronic inflammatory disorders. The maintenance of tissue integrity and function represent a complex challenge that requires both resilience and adaptation. Under steady-state conditions, tissue resilience is, in part, mediated by innate and adaptive immunity to the microbiota, which reinforces barrier function and immunity (5).

Our results show that adaptation of tissue to injuries can also be mediated by immunity to the microbiota, a fundamental but poorly understood class of immunity. Notably, we found that homeostatic immunity to bacteria or fungal commensals is characterized by the coexpression of paradoxical programs, allowing commensal-specific T cells, when entering and persisting within tissues, to adopt a type 17 program compatible with tissue homeostasis and immunity while maintaining a type 2-poised state. As such, in the context of injury and consequent exposure to inflammatory mediators and cognate antigens, commensal-specific T cells rapidly release type 2 cytokines, allowing these cells to exert pleiotropic

and contextual functions including tissue repair. Thus, we describe a tissue checkpoint that relies on the remarkable plasticity and adaptability of tissue-resident commensal-specific T cells. We propose that this feature may also have important implications in the etiology of tissue-specific inflammatory disorders. Given the extraordinary number of both commensal-derived antigens and T cells at barrier sites, such a feature may represent a fundamental component of host immunity.

Materials and methods

Mice

Wild-type (WT) C57BL/6 Specific Pathogen Free (SPF) mice were purchased from Taconic

Contour plots represent IL-5 and IL-17A production potential of IL-17A^{FM+} Tc17 (CD8⁺CCR6⁺eYFP⁺) or IL-17A^{FM-} Tc17 (CD8⁺CCR6⁺eYFP⁻) T cells after i.d. injection of PBS or IL-18. (B) Frequencies of T_c17 cells with IL-17A- or IL-5-producing potential from the skin of *S. epidermidis*-colonized IL-17A^{FM} mice after i.d. injection of PBS or IL-18. (C) Absolute cell number of IL-5- and IL-13-producing lymphocyte subsets in the skin of *S. epidermidis*-colonized wild-type mice after i.d. injection of IL-18. Data are means \pm SD of five mice per group. (D) Absolute number of eosinophils from the skin of *S. epidermidis*-colonized wild-type mice after i.d. injection with PBS or IL-18, and i.p. injection with anti-IL-5 or isotype control. (E and F) Naïve and *S. epidermidis*-colonized wild-type and II13^{-/-} mice, with or without adoptive transfer of Bowie^{Tg} CD8⁺ T cells before colonization and isotype or anti-IL-13 antibodies at the time of wounding, were subjected to back-skin punch biopsy. Epithelial tongue length of wound bed-infiltrating keratinocytes was quantified 5 days after wounding. (G) Pathway analysis using differentially expressed genes between d3 isotype and d3 anti-IL-13 wounding groups was performed using Enrichr and graphed according to enrichment score for significant Reactome biological processes. Numbers in representative plots indicate means \pm SD. Bar graphs show means \pm SD. Data represent at least two experiments with three to seven mice per group. *P < 0.05, **P < 0.01, ***P < 0.001 as calculated using one-way [(A), (B), (D)] or two-way [(E), (F)] ANOVA with Holm-Sidak multiple-comparison test.

Biosciences. *Gata3*^{fl/fl} (37), *Foxp3*^{YFP-Cre} (38) and *Il17a*^{Cre} (26) have been previously described and were generously provided by J. Zhu (NIAID, NIH), A. Rudensky (Memorial Sloan Kettering Cancer Center), and B. Stockinger (Francis Crick Institute), respectively. *Foxp3*^{grt} (39), CD45.1 (B6.SJL-Ptprc^a Pepc^b/BoyJ), *Tcrα*^{-/-} (B6.129S2-Tcrα^{tm1Mow}/J) (40), CD45.1 *Rag1*^{-/-}, *Il13*^{-/-} (41), and CreERT2-*Gata3*^{fl/fl} mice (42) were purchased from the

NIAID-Taconic Exchange. *Tcrα*^{+/−} mice were generated by breeding *Tcrα*^{−/−} mice with C57BL/6 WT mice. *Foxp3*^{DTR} (B6.129(Cg)-Foxp3^{tm3(DTR/GFP)} Ayr/J) (41) and *R26R*^{eYFP} (B6.129X1-Gt(ROSA) 26Sor^{tm1(EYFP)Cos}/J) (43) mice were purchased from The Jackson Laboratory. *CD4*^{Cre}*Il18r1*^{fl/fl} and *Il18r1*^{fl/fl} control mice were kindly provided by G. Trinchieri (NCI, NIH). All mice were bred and maintained under SPF conditions at an

American Association for the Accreditation of Laboratory Animal Care (AAALAC)-accredited animal facility at NIAID and housed in accordance with the procedures outlined in the Guide for the Care and Use of Laboratory Animals. All experiments were performed at NIAID under an Animal Study Proposal (LPD-11E or LPD-68E) approved by the NIAID Animal Care and Use Committee. Sex- and age-matched mice between

6 and 35 weeks of age were used for each experiment.

Commensal culture and colonization

Staphylococcus epidermidis NIHLM087 (44) was cultured for 18 hours in Tryptic Soy Broth at 37°C. *Candida albicans* (8) was cultured for 18 hours in Tryptic Soy Broth at 37°C (shaking 180 rpm). For colonization with commensal microbes, as before (45), each mouse was topically associated by placing 5 ml of culture suspension (approximately 10⁹ CFU/ml) across the entire skin surface (approximately 36 cm²) using a sterile swab. Application of commensal microbes was repeated every other day a total of four times. Skin tissue was analyzed 14 days after initial colonization, unless otherwise indicated.

Inducible deletion of *Gata3*

Deletion of *Gata3* in CreERT2*Gata3*^{f/f} mice was induced by intraperitoneal injection of 5 mg tamoxifen in a corn oil–ethanol (90:10) mixture daily for 3 days before cellular isolation and subsequent analysis.

Global *T_{reg}* cell depletion

Naïve or *S. epidermidis*–colonized *Foxp3*^{DTR} mice received ~1 µg (50 µg/kg) of diphtheria toxin (Sigma-Aldrich) in phosphate-buffered saline (PBS), or PBS alone, by intraperitoneal (i.p.) injection on days 3, 5, 7, and 9 after initial *S. epidermidis* colonization. Flow cytometric analysis of skin leukocytes was performed 12 days after initial colonization.

Generation of Bowie^{Tg} mice

Tcrα^{+/-} mice were colonized with *S. epidermidis*, and CD8⁺CCR6⁺ T cells were isolated from skin tissue by fluorescence-activated cell sorting (FACS) and subjected to single-cell sequencing of TCR α and β chains (46). Clonal TCR pairs were identified and used in a hybridoma reconstitution screening assay to identify *S. epidermidis*-reactive TCR heterodimers. A single *S. epidermidis*-specific TCR pair was cloned into a hCD2-expression vector (47) and used to generate TCR-transgenic mice (Bowie^{Tg}), to track *S. epidermidis*-specific T cells in vivo.

Adoptive transfer of Bowie^{Tg} CD8⁺ T cells

Bowie^{Tg} mice were backcrossed to a CD45.1 *Rag1*^{-/-} background to exclude the possibility of dual TCR expression and facilitate identification of transferred cells. Recipient mice (CD45.2) received 4 × 10⁵ Bowie^{Tg} CD45.1 *Rag1*^{-/-} CD8⁺ T cells by intravenous injection 24 hours before the first application of *S. epidermidis*.

Parabiosis experiments and surgery

Congenically distinct, age- and weight-matched mice were co-housed for 2 weeks before colonization with *S. epidermidis*. Both mice were colonized to control for bacterial spread. Forty days after initial colonization, parabiosis surgery was performed as described (10). Briefly, mice were sedated and longitudinal incisions were made from the elbow to the knee joint of each mouse. Excess skin

was removed and mice were joined at the joints. The skin of the two animals was then connected and sutured together. Animals were kept on oral antibiotics for 2 weeks and remained conjoined for 90 to 95 days before analysis. Analysis was performed on ear pinnae skin tissue.

Acute intradermal challenge

S. epidermidis–colonized mice were anesthetized with ketamine-xylazine and injected intradermally (10 µl per ear pinnae) with either sterile PBS (vehicle control), 250 ng of carrier-free recombinant IL-18 (R&D Systems), or 500 ng of chitin (Sigma-Aldrich). Unless otherwise indicated, skin tissue was analyzed for cytokine production potential 48 hours after injury.

Sand fly bite exposure

S. epidermidis–colonized mice were exposed to sand fly bites as described (48). Briefly, mice were anesthetized with ketamine-xylazine. Twenty female *Lutzomyia longipalpus* were transferred to plastic vials (volume 12.2 cm², height 4.8 cm, diameter 1.8 cm) covered at one end with 0.25 mm of nylon mesh. Specially designed clamps were used to bring the mesh end of each vial flat against the ear, allowing flies to feed on exposed skin for a period of 1 hour in the dark at 26°C and 50% humidity. The number of flies with blood meals was employed as a means of checking for equivalent exposure to bites among animals. At indicated time points after exposure, tissues were analyzed for cytokine production.

Ex vivo cytokine screening

CD4⁺ and CD8⁺ T cell subsets from the skin of *S. epidermidis*– or *C. albicans*–colonized mice were isolated by FACS (> 97% purity) and cultured for 24 hours in the presence of cytokines (IL-1α, IL-1β, IL-18, IL-25, IL-33, or TSLP; R&D Systems) (10 ng/ml) and presence or absence of TCR stimulation (1 µg/ml plate bound anti-CD3 mAb, clone 145-2C11). Culture supernatants were assayed for cytokine production by FlowCytomix bead array (eBioscience).

Tissue processing

Cells from the skin-draining lymph nodes, spleen, and ear pinnae were isolated as described (6). Cells from lymph nodes and spleen were mashed through a 70-µm cell strainer to generate single-cell suspensions. Ear pinnae were excised and separated into ventral and dorsal sheets. Ear pinnae were digested in RPMI 1640 media supplemented with 2 mM l-glutamine, 1 mM sodium pyruvate, 1 mM non-essential amino acids, 50 µM β-mercaptoethanol, 20 mM HEPES, 100 U/ml of penicillin, 100 mg/ml of streptomycin, and 0.25 mg/ml of Liberase TL purified enzyme blend (Roche), and incubated for 90 min at 37°C and 5% CO₂. Digested skin sheets were homogenized using the Medicon/Medimachine tissue homogenizer system (Becton Dickinson).

In vitro restimulation

For detection of basal cytokine potential, single-cell suspensions from various tissues were cul-

tured directly ex vivo in a 96-well U-bottom plate in complete medium (RPMI 1640 supplemented with 10% fetal bovine serum, 2 mM l-glutamine, 1 mM sodium pyruvate, 1 mM nonessential amino acids, 20 mM HEPES, 100 U/ml penicillin, 100 mg/ml streptomycin, and 50 µM β-mercaptoethanol) and stimulated with 50 ng/ml of phorbol myristate acetate (PMA) (Sigma-Aldrich) and 5 mg/ml of ionomycin (Sigma-Aldrich) in the presence of brefeldin A (1:1000, GolgiPlug, BD Biosciences) for 3 hours at 37°C in 5% CO₂. After stimulation, cells were assessed for intracellular cytokine production as described below.

Flow cytometric analysis

Single-cell suspensions were incubated with combinations of fluorophore-conjugated antibodies against the following surface markers: CCR6 (29-2L17), CD3ε (145-2C11), CD4 (RM4-5), CD8β (53-6.7), CD11b (M1/70), CD19 (6D5), CD44 (IM7), CD45 (30-F11), CD45.1 (A20), CD45.2 (104), CD69 (H1.2F3), CD103 (2E7), MHCII (M5/114.15.2), TCRβ (H57-597), and/or Thy1.2 (30-H12) in Hank's buffered salt solution (HBSS) for 20 min at 4°C (RT for 30 min for CCR6) and then washed. LIVE/DEAD Fixable Blue Dead Cell Stain Kit (Invitrogen Life Technologies) was used to exclude dead cells. Cells were then fixed for 30 min at 4°C using BD Cytofix/Cytoperm (Becton Dickinson) and washed twice. For intracellular cytokine staining, cells were stained with fluorophore-conjugated antibodies against IFN-γ (XMG-1.2), IL-5 (TRK5), IL-13 (eBio13A), and IL-17A (eBio17B7) in BD Perm/Wash Buffer (Becton Dickinson) for 60 min at 4°C. For transcription factor staining, cells were fixed and permeabilized with the Foxp3/Transcription Factor staining buffer set (eBioscience) and stained with fluorophore-conjugated antibodies against Foxp3 (FJK-16s), GATA-3 (L50-823 or TWAJ), RORγt (B2D), or T-bet (eBio4B10) for 45 min at 4°C. Each staining was performed in the presence of purified anti-mouse CD16/32 (clone 93) and purified rat gamma globulin (Jackson Immuno-research). All antibodies were purchased from eBioscience, Biolegend, BD Biosciences, or Miltenyi Biotec. Cell acquisition was performed on a BD Fortessa X-20 flow cytometer using FACSDiva software (BD Biosciences) and data were analyzed using FlowJo software (TreeStar).

RNA staining

Skin tissue single-cell suspensions were analyzed for mRNA and protein expression using the PrimeFlow RNA assay (eBioscience) and standard mouse probe sets for *Ifng*, *Il5*, *Il13*, and *Il17a*, as per manufacturer's instructions for 96-well-plate staining.

Tetramer-based cell enrichment

f-MIIINA:H2-M3-specific CD8⁺ T cells from secondary lymphoid organs were subjected to magnetic bead based enrichment, as previously described (49). Briefly, spleen and lymph node cells from parabiotic pairs were stained for 1 hour at room temperature with f-MIIINA:H2-M3-streptavidin-phycocerythrin (PE) tetramer. Samples were then incubated with anti-PE beads (Miltenyi Biotech)

and enriched for bead-bound cells on magnetized columns.

RNA-sequencing and transcriptome analysis

T cells were isolated by flow cytometric cell sorting from the ear skin tissue of C57BL/6 mice 2 weeks after colonization with *S. epidermidis* NIHLM087. Groups included: T_{c1} (Viable Lineage⁻CD45⁺CD90.2⁺TCR β^+ CD8 β^+ CCR6 $^-$) and T_{c17} cells (Viable Lineage⁻CD45⁺CD90.2⁺TCR β^+ CD8 β^+ CCR6 $^+$). Sorted cells were lysed in Trizol reagent and total RNA isolated by phenol-chloroform extraction with GlycoBlue as a co-precipitant (7 μ g per sample; Life Technologies). Single-end libraries were prepared with 0.25 to 1 μ g of total RNA using the TruSeq RNA Sample Preparation Kit V2 and sequenced for 50 cycles with a HiSeq 2500 instrument (4 to 6 samples multiplexed per lane; Illumina). Sequencing quality of the raw read data was assessed using FASTQC v0.11.5. Using a custom Perl script, 10 bp were trimmed from the 3' end of the 50-bp reads. Subsequently, FASTQ files were used as input for RSEM v1.3.0 (50) (internally configured to use the bowtie aligner, v1.1.1). Expected read counts from RSEM were imported into the DESeq2 Bioconductor package (51), normalized using the geometric-mean based approach built into this package and then tested for differential expression between groups using a Wald test with multiple testing correction using Benjamini-Hochberg false discovery.

ATAC sequencing and epigenome analysis

T cells were isolated as for RNA sequencing. ATAC-seq was performed according to a published protocol (16). ATAC-seq reads from two biological replicates for each sample were mapped to the mouse genome (mm10 assembly) using STAR (52). Duplicate reads were removed using FastUniq (53), and reads mapping to mitochondrial loci removed based upon ENCODE blacklists. Regions of open chromatin were identified by MACS (version 1.4.2) using a *P*-value threshold of 1×10^{-5} . Only regions called in both replicates were used in downstream analysis. Downstream analysis and heatmap generation were performed with the Hypergeometric Optimization of Motif EnRichment program (HOMER) version 4.8 (54).

Single-cell RNA sequencing

T cells were isolated as for bulk RNA sequencing, from *S. epidermidis*-colonized IL-17A-fate-mapping mice, with three groups: T_{c1} (Viable Lineage⁻CD45⁺CD90.2⁺TCR β^+ CD8 β^+ CCR6 $^-$), T_{c17} IL-17A^{FMT}⁺ (Viable Lineage⁻CD45⁺CD90.2⁺TCR β^+ CD8 β^+ CCR6 $^+$ eyFP $^+$), and T_{c17} IL-17A^{FMT}⁺ (Viable Lineage⁻CD45⁺CD90.2⁺TCR β^+ CD8 β^+ CCR6 $^+$ eyFP $^+$). Freshly isolated cells were encapsulated into droplets, and libraries prepared using Chromium Single Cell 3' Reagent Kits v2 (10X Genomics). The generated scRNA-seq libraries were sequenced using 26 cycles of Read 1, 8 cycles of i7 Index, and 98 cycles of Read2 with a HiSeq 3000 (Illumina).

Single-cell RNA sequencing analysis

Sequence reads were processed and aggregated using Cell Ranger software. Aggregated data were further analyzed using Seurat (55).

Confocal microscopy

Ear pinnae were split with forceps, fixed in 1% paraformaldehyde in PBS (Electron Microscopy Sciences) overnight at 4°C, and blocked in 1% BSA + 0.25% Triton X in PBS for 2 hours at room temperature. Tissues were first stained with anti-CD4 (RM4-5, eBioscience), anti-CD8α (clone 53-6.7, eBioscience), anti-CD45.1 (A20, eBioscience), anti-CD49f (GoH3, eBioscience), and/or anti-GFP (A21311, Life Technologies) antibodies overnight at 4°C, washed three times with PBS and then stained with 4,6-diamidino-2-phenylindole (DAPI, Sigma-Aldrich) overnight before being mounted with ProLong Gold (Molecular Probes) antifade reagent. Ear pinnae images were captured on a Leica TCS SP8 confocal microscope equipped with HyD and PMT detectors and a 40 \times oil objective (HC PL APO 40 \times /1.3 oil). Images were analyzed using Imaris software (Bitplane).

Back-skin wounding and epifluorescence microscopy of back-skin wounds

Tissue wounding and quantitation of wound healing were performed as previously described (56). Briefly, male mice in the telogen phase of the hair cycle were anesthetized and punch biopsies performed on back skin. Dorsal hair was shaved with clippers and a 6-mm biopsy punch was used to partially perforate the skin. Iris scissors were then used to cut epidermal and dermal tissue to create a full thickness wound in a circular shape. Back-skin tissue was excised 5 days after wounding, fixed in 4% paraformaldehyde in PBS, incubated overnight in 30% sucrose in PBS, embedded in OCT compound (Tissue-Tek), frozen on dry ice, and cryo-sectioned (20- μ m section thickness). Sections were fixed in 4% paraformaldehyde in PBS, rinsed with PBS, permeabilized with 0.1% Triton X-100 in PBS (Sigma-Aldrich), and blocked for 1 hour in blocking buffer (2.5% Normal Goat Serum, 1% BSA, 0.3% Triton X-100 in PBS). Primary antibody to Keratin 14 (chicken, Poly9060, 1:400, Biologen) was diluted in blocking buffer with rat gamma globulin and anti-CD16/32 and incubated overnight. After washing with PBS, a secondary antibody conjugated with Alexa647 (goat anti-chicken, Jackson ImmunoResearch) was added for 1 hour at room temperature. Slides were washed with PBS, counterstained with DAPI and mounted in Prolong Gold. Wound images were captured with a Leica DMI 6000 widefield epifluorescence microscope equipped with a Leica DFC360X monochrome camera. Tiled and stitched images of wounds were collected using a 20 \times /0.4NA dry objective. Images were analyzed using Imaris software (Bitplane).

In vivo cytokine blockade

Naïve or *S. epidermidis*-colonized WT or *Il13*^{-/-} mice received 0.5 mg of anti-IL-13 monoclonal antibody (clone 262A-5-1, Genentech) or mouse IgG1 isotype control (clone MOPC-21, BioXCell),

or 1 mg of anti-IL-5 monoclonal antibody (clone TRFK5, BioXCell) or rat IgG1 isotype control (clone TNP6A7, BioXCell), or 1 mg of anti-IL-18 monoclonal antibody [clone SK113AE-4 (57)] or isotype control by i.p. injection 1 day before skin injury.

Total tissue RNA-seq

A ~1-mm skin region surrounding the wound site was microdissected at indicated time points after wounding, submerged in RNAlater (Sigma-Aldrich), and stored at -20°C. Total tissue RNA was isolated from skin tissue using the RNeasy Fibrous Tissue Mini kit (Qiagen), as per manufacturer's instructions. A 3' mRNA sequencing library was prepared using 200 to 500 ng of total input RNA with the QuantSeq 3' mRNA-Seq Library Prep Kit FWD for Illumina (Lexogen) as per manufacturer's instructions. Libraries were quantified using an Agilent Tapestation (High Sensitivity D1000 ScreenTape) and Qubit (Thermo Fisher Scientific). Libraries ($n = 20$) were pooled at equimolar concentrations and sequenced on an Illumina Nextseq 500 using the High Output v2 kit (75 cycles). Resultant data was demultiplexed on Illumina Basespace server using blc2fastq tool. The reads from the Illumina Next-seq sequencer in fastq format were verified for quality control using FastQC software package, aligned to mouse GRCM38 using RSEM package (50) calling STAR aligner (52). The RSEM expected counts were rounded to the nearest integer value and the transcripts with zero counts across all samples filtered out. Differential expression analysis and principal components analysis was performed using DESeq2 (51).

Statistics

Groups were compared with Prism V7.0 software (GraphPad) using the two-tailed unpaired Student *t* test, one-way analysis of variance (ANOVA) with Holm-Šidák multiple-comparison test, or two-way ANOVA with Holm-Šidák multiple-comparison test where appropriate. Differences were considered to be statistically significant when $P < 0.05$.

ACKNOWLEDGMENTS

We thank the National Institute of Allergy and Infectious Diseases (NIAID) animal facility staff; K. Holmes, E. Stregevsky, and T. Hawley (NIAID Flow Cytometry facility); G. Gutierrez-Cruz, S. Dell'Orso, and H.-W. Sun (NIAMS Genome Analysis Core facility); J. Kehr for editorial assistance; K. Beach and S. Mistry for technical assistance; and I. Förster (University of Bonn) for generous provision of the anti-IL-18 hybridoma. f-MIIINA-H2-M3-tetrramer reagents were obtained from the NIH Tetramer Core Facility. This study used the Office of Cyber Infrastructure and Computational Biology (OCICB) High Performance Computing (HPC) cluster at NIAID and the high-performance computational capabilities of the Biowulf Linux cluster at NIH. **Funding:** Supported by the NIAID Division of Intramural Research (ZIA-AI001115, ZIA-AI001132) (Y.B.); the Division of Intramural Research of the National Institute of Arthritis and Musculoskeletal and Skin Diseases (NIAMS; ZIA-AR041159, ZIA-AR041167) (O.J.H.); a National Psoriasis Foundation Early Career Research Grant (O.J.H.); the National Institute of General Medical Sciences (NIGMS) Postdoctoral Research Associate (PRAT) fellowship program (J.L.L.); a European Molecular Biology Organization (EMBO) fellowship (S.T.); and Collège des Enseignants de Dermatologie Français, Société Française de Dermatologie, Philippe Foundation, and Fondation pour la Recherche Médicale (C.H.). **Author contributions:** O.J.H. and Y.B. designed the study, experiments, and wrote the manuscript; O.J.H. performed the experiments and analyzed the data; J.L.L., S.-J.H., N.B., H.-Y.S., M.S., S.K.S., A.L.B., M.E., S.T., F.V.L., C.H., N.C., A.P., R.S., and J.J.O. participated in performing experiments, provided intellectual expertise, and helped to interpret experimental results; J.L.L. generated Bowie^{Tg} mice, performed wounding experiments, and analyzed data; H.-Y.S., S.K.S., A.L.B., and C.Y. assisted with RNA-seq and ATAC-seq studies; N.B. and S.T. performed flow cytometric analysis of skin immune cells; S.J.H. performed confocal microscopy analysis; M.S. performed epifluorescence microscopy of wounds; M.E. assisted with wounding experiments; S.J.H. and N.C. performed parabiotic surgeries; F.V.L. shared expertise for the generation of TCR-expressing hybridomas and TCR-transgenic mice; A.P. conducted sand fly exposures; and C.H. performed *C. albicans* experiments. **Competing interests:** Authors declare no competing interests. **Data and materials availability:** Anti-IL-13 (clone 262A-5) is available under a material agreement with Genentech. Anti-IL-18 (clone SK113AE-4) is available from I. Förster under a material agreement with the University of Bonn. The accession number for the RNA-seq and ATAC-seq datasets is NCBI BioProject: PRJNA486019. All other data needed to evaluate the conclusions in this paper are present either in the main text or the supplementary materials.

Commensal-specific T cells are flexible

Barrier tissues, like the skin, are sites where noninvasive commensal microbes constantly interact with resident T cells. These encounters can result in commensal-specific T cell responses that promote, for example, host defense and tissue repair. Harrison *et al.* show that subsets of skin-resident commensal-specific interleukin-17A-producing CD4⁺ and CD8⁺ T cells have a dual nature: They coexpress transcription factors that direct antagonistic antimicrobial (type 17) and antiparasite and pro-tissue repair (type 2) programs. When skin is damaged, epithelial cell alarms license type 17 T cells to turn on type 2 cytokines. Thus, commensal-specific type 17 T cells can direct antimicrobial activity under homeostatic conditions but rapidly turn on tissue repair in the context of injury.
